ABSTRACT
Specification languages have long featured ways to describe what does not change when an imperative procedure is executed: the so-called frame problem. Solutions to the frame problem are needed for formal verification in imperative programming, as otherwise a verification would not be able to accumulate information from one statement to the next. Region logic is one of the approaches to solving the frame problem. We present a modified version of region logic with fine-granularity and introduce conditional effects that allows one to specify more precise frame conditions.

Region logic, framing, formal specification, formal verification, Hoare logic

1. INTRODUCTION
In a formal specification language, frame properties describe what is allowed to change and thus what does not change when an imperative procedure is executed [5]. There are two common ways of expressing frame properties. One is a clause in a procedure’s specification (such as modifies, assignable and wr) to specify write effects [2, 3] by listing a set of abstract locations that may be changed in a method. Another is using post conditions, such as a = old(a), which says a’s value is the same as the value before the method call. Dynamic frames [7, 8] techniques, such as Dafny [10] and region logic [2, 3], use unconditional effects that usually over-approximate write effects. That means locations where the values are preserved in some conditions also appear in frame conditions. Consequently, one has to specify which parts of the specific objects are not changed in post-conditions.

We explain the problem of unconditional effects by a toy example written in FRL. It is an adaption of the Dafny’s solution [10] to the problem 4 in the VSI benchmark [7]. The purpose of this example is to overview the FRL language and to illustrate the issues of unconditional effects. The detailed implementations of the functions and methods are omitted. And we also only show some excerpts of the specifications that are related to the issues that we are discussing in this paper. The FRL1 programming language is a sequential programming language. A FRL program can consist of a set of classes with fields and methods. The example in Fig. 1 shows a generic map implemented by an acyclic list. The keywords requires and ensures are used to specify method preconditions and post-conditions, and the keywords reads and modifies are used to specify read effects [2, 3] and write effects. Read effects describe a set of locations that expressions depend on. Method Init is a map’s constructor; it can be used on the right-hand side of an assignment statement. The use of fresh in its postcondition allows one to add newly allocated Node to fpt. The ghost variable fpt, declared as type region, is used to store abstract locations of a map, which is a map’s dynamic frame. fpt needs to be explicitly updated when the map changes, as in method Add. Such statements involving regions cause ghost state changes, which must not affect the programs’ control flow. For example, regions cannot appear in the tests of branching statements. Function Valid describes the structure of a map by logic formulas. In this example, Valid is considered as an invariant, which must be kept valid after a map is initialized, and before and after each method call. The detailed implementation of Valid is omitted. The method Add updates the value of the key, k, with a new value, v, if it is already in the map, otherwise, a new key-value pair, (k, v), is prepended to the map.

The frame condition, modifies fpt, means all the locations in the map may be modified by the method Add. It over-approximates Add’s real write effect, since if k is held by a key-value pair, p, in the map, only the location region[p.val] will be changed; otherwise only the location region[this.fpt] will be changed.

FRL language is a blend of Dafny [10] and VERL [11].

1The work of the first two authors is supported in part by US NSF under grant CCF-0916715.
So one has to specify that the value of the extra locations are preserved. For example, the specification in line 22 means all the values of the key-value pairs, whose key is not k, are preserved. The expression \texttt{old}(fpt) denotes the values in the pre-state. That is the value evaluated before \texttt{Add} executes. We call such a postcondition a \textit{make-up frame condition}. The condition \( o.k = \texttt{old}(o.key) \) in line 21 is also a make-up frame condition. If we allow one to specify frame conditions more precisely, then the make-up frame conditions can be avoided, such as the following frame condition and postcondition:

\begin{verbatim}
modifies if \texttt{Find}(key) = null then region(this.fpt)
else region(\texttt{Find}(key).val);
ensures Valid() && fresh(fpt - old(fpt));
ensures \exists region(o.*). \subseteq fpt.(o.key = key && o.val = val);
\end{verbatim}

The frame condition uses the pure method \texttt{Find} that returns the reference that holds k if it is in the map, otherwise returns null reference. The technique of pure methods in region logic is discussed in Banerjee and Naumann’s work \cite{9}, and is out of the scope of this paper. The frame condition says if there is an object, \( p \), that holds the key, \( k \), then the location region(\( p \).val) can be modified, otherwise the location region(this.fpt) can be modified. Because the frame condition is much more precise than the one in Fig. 1, the make-up frame conditions are avoided in the post-condition. The conditional effect is caused by conditional statements in the program where mutually exclusive conditions branches the execution traces of programs. Our CONMASK1 and CONMASK2 rules discussed in section 5 can drop the condition. Therefore conditional effects do not necessarily increase the complexity of the composition of effects.

\textbf{Contribution:} in this paper, we propose a fine-grained region logic. It defines a region as a set of locations, that is as ghost state in a son, we try to use the same symbols and definitions as the work \cite{3}, 2. RELATED WORK

Our work is an adaption of region logic \cite{2,3}. To ease comparison, we try to use the same symbols and definitions as the work \cite{3}, such as \texttt{fpt} function and the separator \( / \). Our work has two major differences from region logic. (1) In region logic, regions, \( G \), are sets of references, possibly containing \texttt{null} \cite{3}. For example, \( \{o\} \) is a region containing a singleton object \( o \). Image expressions \( o.f \) denotes the location which corresponds to our region(\( o.f \)). Our work made an extension to region logic to uniformly use sets of locations, which one can think of as sets of pairs of object references and field names; for this reason we call our region logic a “fine-grained” region logic. Using sets of locations is also a good match for specification languages such as JML \cite{6}, in which frames are specified in terms of sets of locations. The pair \( \{\texttt{null},f\} \) is not allowed in the regions of our languages’ semantics. Since we re-defined region expressions, the \texttt{fpt} function and \( / \) are re-defined. (2) The work on region logic \cite{2,3} does not consider conditional effects. Recent work \cite{1} considers a logical analysis of framing for specifications with pure method calls. Our work can also be used in method calls with side effects. We re-defined the frame judgments and the new \( / \) definitions based on our new syntax. Due to the introduction of conditional effects, we revised the definition of the \texttt{POSTOFR}, \texttt{FRTPOST}, \texttt{VARMASK} and \texttt{FIELDMASK} rules, and also introduce the \texttt{CONEFF}, \texttt{CONMASK1} and \texttt{CONMASK2} rules in proving program correctness. These are our contributions.

\begin{verbatim}
class Node<Key,Value> {  
  var key: Key; var val: Value;
  var next: Node<Key,Value>;
  
  class Map {  
    var head : Node<Key, Value>; 
    ghost var fpt: region;
    
    function Valid() : bool( ... );
    constructor Init() {
      modifies region(this.*);
      ensures Valid() && fresh(fpt - region(this.*));
      {  
        fpt := region(this.*); head := null;
      }
    }
    method Add(k: Key, v: Value) {
      requires Valid();
      modifies fpt;
      ensures Valid() && fresh(fpt - old(fpt));
      ensures \exists region(o.*) \subseteq fpt.
      (old(o.key) = k => o.val = v && o.key = old(o.key));
      ensures \forall region(o.*) \subseteq old(fpt).
      (old(o.key) != k => o.key = old(o.key) &&
      o.val = old(o.val));
    
    if (p = null) {
      var h := new Node<Key,Value>;
      h.key := k; h.val := v; h.next := head;
      fpt := fpt + region(h.*);
    } else {
      p.val := val;
    }
    
    pure method Find(k: Key) returns (p: Node<Key,Value>) {
      requires Valid();
      reads fpt;
      ensures p = null => \forall region(o.*) \subseteq fpt.(o.key = k);
      ensures p != null => region(p.*) \subseteq fpt && p.key = k;
      {  
        ...
      }
    }
  }

  Figure 1: The toy example of Map

The work \cite{9,12,13} allows one to write specifications for different cases. For example, the keyword \texttt{also} is used in \cite{6}. We consider it as a syntactic sugar for our conditional effects.

3. AN OVERVIEW OF FRL

The FRL \footnote{FRL language is a blend of Dafny \cite{10} and VERL \cite{11}.} programming language is a sequential programming language. A FRL program can consist of a set of classes with fields and methods. The keywords \texttt{requires} and \texttt{ensures} are used to specify method preconditions and postconditions, and the keywords \texttt{reads} and \texttt{modifies} are used to specify read effects \cite{2,3} and write effects. Read effects describe a set of locations that expressions depend on. The \texttt{decreases} clause specifies termination conditions for recursive methods.

The code in Fig. 2 shows a linked-list example written in FRL. To simplify the presentation, the specification only describes the shape of a linked-list. Method \texttt{Init} is a list’s constructor; it can be used on the right-hand side of an assignment statement. The use of \texttt{fresh} in its postcondition allows one to add newly allocated \texttt{Node} to \texttt{fpt}. The ghost variable \texttt{fpt}, declared as type \texttt{region}, is used to store abstract locations of a linked list, which is a list’s dynamic frame. \texttt{fpt} needs to be explicitly updated when the list changes, as in method \texttt{Append}. Such statements involving regions cause \texttt{ghost} state changes, which must not affect the programs’ control flow. For example, regions cannot appear in the tests.
of branching statements. Function \(\text{Valid}\) describes the structure of a linked-list by logic formulas. In this example, \(\text{Valid}\) is considered as an invariant, which must be kept valid after a list is initialized, and before and after each method call. The frame of \(\text{Append}\) is specified by a conditional effect. One could specify it by \(\text{modifies} n.\text{fpt}\). But the problem is when \(n = \text{null}\), \(n.\text{fpt}\) dereferences null reference, which makes no sense. The condition \(n \neq \text{null}\) is necessary to have meaningful frame conditions in the common programming concepts, although the work of region logic [2,3] defines null.\(\text{fpt}\) as an empty set.

4. PROGRAMMING LANGUAGE

This section presents the FRL programming language for which we formalize the programming logic.

4.1 Syntax

Fig. 3 shows the syntax of the FRL language. A program consists of a statement \(S\) in the context of some class declarations. A class consists of fields and methods. A field is declared with type: integer, boolean, a user-defined datatype, or region. A method is declared in a class. In a method implementation, there are local variable declarations, update statements, condition statements, and loop statements. Unlike the type \(\text{rgn}\) in region logic [2,3], which ranges over sets of references, the type \(\text{region}\) stores locations of fields. Each field’s location is represented by a pair of an allocated reference and a field name. The region expression \(\text{region}\[]) denotes the empty region. For each \(x\) that evaluates to a non-null object, a region expression of the form \(\text{region}[,f]\) denotes a singleton set that stores the location of field \(f\) in the object that is the value of \(x\). The form \(\text{region}[,\ast]\) denotes a set containing the abstract locations represented by the reference \(x\) and all its fields. A region expression of the form \(\text{filter}[,f,C]\) denotes one of the two meanings: if \(f\)’s type is \(\text{region}\), it is the union of all the regions \(o.f\), where \((o.f)\) is in \(RE\) and \(o\) has type \(C\); otherwise, it is the location of form \((o.f)\), where each object reference, \(o\), has the type \(C\). A region expression of the form \(\text{filter}[,f,C]\) denotes the subset of \(RE\) with references of type \(C\). For example, let \(RE = \{o_1.f_1, o_1.f_2, o_2.f_1\}\), where only \(o_1\) has type \(C\), then \(\text{filter}(RE,C) = \{o_1.f_1, o_1.f_2\}\). The operators +, -, and \(\ast\) denote union, difference and intersection respectively.

5. ASSERTION LANGUAGE

In this section, we formalize RSL’s assertion language.

5.1 Syntax and semantics of assertions

The syntax of assertions is shown in Fig. 9. We call the first three \(\text{atomic assertions}\). Quantification is restricted in the syntax. Quantified variables may denote an \(\text{int}\), or a location drawn from a region. The typing rules for assertions are in Fig. 10. The semantics of assertions are shown in Fig. 11. \(RE_1 \subseteq RE_2\) means \(RE_1\) is subregion of \(RE_2\). Note that the semantics identifies errors (\(\text{err}\)) with false.
\[
\Gamma \vdash x : T \,\text{where} \, (\Gamma \, x) = T \quad \Gamma \vdash n : C \,\text{where} \, \text{isClass}(C) \quad \Gamma \vdash : \text{int} \\
\Gamma \vdash E_1 : T_1 \quad \Gamma \vdash E_2 : T_2 \quad \Gamma \vdash : T_1 \rightarrow T_2 \rightarrow T \\
\Gamma \vdash E_1 \oplus E_2 : T
\]

\text{false} & \text{otherwise}
\end{cases}
\end{align*}
\]

Figure 11: Semantics of Assertions

5.2 EFFECTS

Effects (ε) are used in frame conditions. The keyword modifies specifies write effects and reads specifies read effects. fresh(RE) means all the locations in RE did not exist (were not allocated) in the pre-state. We introduce a conditional effect: if E then ε₁ else ε₂: it denotes that if E ̸= 0, the effect is ε₁, otherwise the effect is ε₂.

ε := (empty) | ε₁ | if E then ε₁ else ε₂ | reads RE | reads x | modifies RE | modifies x | fresh (RE)

The latter five forms are called atomic effects. We omit modifies and reads when the context is obvious. For example, in a modifies clause we write if E then RE else x instead of if E then modifies RE else modifies x. And if E then ε is an abbreviation of if E then ε else (ε). A verified method must make sure that the actual write effect in the method is the sub-effect of the specified effect in the frame condition. Consider verifying and's frame condition in Fig. 1. The frame obligation in line 30 is: region(this.fpt) ≤ (if Find(k) = null then region(this.fpt) else region(Find(k).val)) with the assumption Find(k) = null. We use the sub-effect rule [4] to reason about such cases. It encodes the standard properties of sets.

5.3 Framing

Let R be the region that the frame condition of a method, m, specifies in a given state. R contains the locations that may be modified in m. The locations that are preserved are the compliment of R, written R. Let R' be locations that may be used in evaluating an assertion, P, written readsR'fmp P. If R' ⊆ R, i.e., R'!!R, then P’s validity is preserved after m is called. We use fmp in Fig. 14 to define R' for expressions, atomic region expressions, and atomic assertions. The frame judgment, P ⊢^T δ fmp Q, means that in the type context, Γ, δ contains the locations that are needed to evaluate Q in a state that satisfies P. Note that we use δ to denote reads effects and ε to denote write effects, and Γ is omitted when the type context is the same in the judgment. Fig. 15 shows the judgment for non-atomic region expressions and assertions.

Definition 1 says that if two states agree on a read effect, δ, then the values of the expressions that depend on δ are identical.

Definition 1. (Agreement on read effects) Let δ be an effect that is type-checked in Γ. Let Γ' ⊇ Γ and Γ'' ⊇ Γ. Let σ and σ' be Γ'-state and Γ''-state respectively. σ and σ' agree on δ, σ ≡ δ', if and only if:

1. for all reads x ∈ δ, σ(x) = σ'(x)
2. for all reads region[x.f] ∈ δ, σ[∀x : int.] = σ'[∀x : int.].
Definition 2 says that if two states agree on a read effect, \( \delta \), then the validity of assertions, \( Q \), that depend on that read effect are preserved under condition, \( P \).

**Definition 2.** (Frame validity) \( P \vdash^r \delta \) from \( Q \) is valid, written \( P \models^r \delta \) from \( Q \), if and only if for all states \( \sigma, \sigma' \), if \( \sigma \equiv^r \sigma' \) and \( \sigma \models^r P \wedge Q \), then \( \sigma' \models^r Q \).

**Lemma 1.** (Frame soundness of expressions) Let \( \sigma \) and \( \sigma' \) be arbitrary states. Let \( E \) be an expression. If \( \sigma \equiv^r \sigma' \), then \( \mathcal{E}[\Gamma \vdash E : T](\sigma) = \mathcal{E}[\Gamma \vdash E : T](\sigma') \).

**Proof.** The proof is straightforward by structural induction on expressions.

**Lemma 2.** (Frame soundness of atomic region expressions) Let \( \sigma \) and \( \sigma' \) be arbitrary states. Let \( RE \) be an atomic region expression. If \( \sigma \equiv^r \sigma' \), then \( \mathcal{R}[\Gamma \vdash RE : region](\sigma) = \mathcal{R}[\Gamma \vdash RE : region](\sigma') \).

**Proof.** The proof is straightforward by structural induction on atomic region expressions.

**Lemma 3.** (Frame soundness of assertions) Every derivable framing judgment is valid.

**Proof.** By induction on a derivation of a framing judgment \( P \vdash \delta \) from \( Q \). The proof is similar to [3]. We leave it as future work.

We use / to define the disjointness on effects in Fig. 17. The region disjoint rules are defined in Fig. 16. We treat \( \text{reads} \) \( \delta \), where \( \delta \) is not a conditional effect, as \( \text{reads if true then} \) \( \delta \) else . For example, let \( RE \) bc if \( x.f=0 \) then \( \text{region} \{ y.f \} \) else region\{} . Suppose \( x \neq y \) and \( x.f \neq 0 \). The separation of \( \text{reads region} \{ y.f \} \) and \( \text{modifies} RE \) is reduced to \( \text{reads region} \{ y.f \} / \text{modifies region} \{} .

**Lemma 4.** Let \( RE_1 \) and \( RE_2 \) be two regions. Let \( \sigma \) be a state. If \( \sigma \equiv^r RE_1 \)!! \( RE_2 \), then \( \text{reads} RE_1 / \text{modifies} RE_2 \) and \( \text{reads} RE_2 / \text{modifies} RE_1 \).

The following lemma says if read effects, \( \delta \), and write effects, \( \epsilon \) are separate, then the values on \( \delta \) are preserved.

**Lemma 5.** (Separator agreement) Let \( \sigma' = \mathcal{M}_S[\Gamma \vdash S : ok(\Gamma)](CT)(\sigma) \). Let \( \epsilon \) be the write effect of ex-
\[ \text{Figure 14: Footprint of expressions, atomic region expressions and atomic assertions} \]

cutting $S$. Let $\delta$ be a read effects, such that $\sigma' \vdash \delta / \epsilon$, then $\sigma \equiv \sigma'$.

\section{PROGRAM CORRECTNESS}

The validity of a Hoare-formula $[P][S][Q][\epsilon]$ means that if a program, $S$, executes from an initial state satisfying $P$, $S$ does not cause an error, and $S$ terminates, then the final state satisfies $Q$, and any change happens in $\epsilon$. For simplicity, we omit modifies when expressing the write effects. It means that if one can prove that a statement, $S$, can have different effects under the complementarity conditions, $E \neq 0$ and $E = 0$, then one can conclude a conditional effect for $S$. Examples of using CONEFF rules are in our technical report \cite{4}. We derive the IF2 rule with the IF rule in the work of region logic \cite{3}:

\begin{align*}
\text{IF} & \vdash \{P \land E \neq 0\} S_1 \{P'[\epsilon]\} [\epsilon] \\
& \vdash \{P \land E = 0\} S_2 \{P'[\epsilon]\} [\epsilon] \\
& \vdash \{P\} \text{if } \epsilon \text{ then } S_1 \text{ else } S_2 \{P'[\epsilon]\} [\epsilon]
\end{align*}

The IF rule can over-approximates write effects in the sense that $\epsilon$ is the union of the write effects of $S_1$ and $S_2$. The derived IF2 rule shows that if one can prove two branches with different effects, then one can prove the IF statement with conditional effects, which gives a more precise frame condition, because the write effects of IF statement is either those of $S_1$ or those of $S_2$ depending on the branch a program actually takes. To derive the rule IF2, we begin with $\vdash \{P \land E \neq 0\} S_1 \{P'[\epsilon]\}$, and $\vdash \{P \land E = 0\} S_2 \{P'[\epsilon]\}$. Using the sub-effect rule, we have $P \land E \neq 0 \vdash \epsilon \leq \text{if } \epsilon \text{ then } S_1 \text{ else } S_2$ and $P \land E = 0 \vdash \epsilon \leq \text{if } \epsilon \text{ then } S_1 \text{ else } S_2$. Then we can derive the IF2 rule by using the IF rule. Fig. 18 and Fig. 19 lists the axioms and structural rules.

Consider the example:

$S \equiv \text{if } t \text{ then } x.f = 5 \text{ else } y.f = 5$

$P \equiv x \neq y \land x.f = 4 \land y.f = 4$

$P' \equiv (t \neq 0 \Rightarrow x.f = 5) \land (t = 0 \Rightarrow y.f = 5)$

$\epsilon \equiv \text{if } t \text{ then } \text{region}[x.f] \text{ else } \text{region}[y.f]$

We do forward reasoning:

\begin{align*}
\{x \neq y \land x.f = 4 \land y.f = 4\} & \quad x \neq y \land x.f = 4 \land y.f = 4 \\
\{t \neq 0 \Rightarrow x.f = 4 \land y.f = 4\} & \quad x.f = 5 \\
\{t \neq 0 \Rightarrow x.f = 5 \land y.f = 4\} & \quad \text{region}[x.f] \\
\{t = 0 \Rightarrow y.f = 5\} & \quad \text{region}[y.f]
\end{align*}

Formula in line 6 implies

$\{t \neq 0 \Rightarrow x = y \land x.f = 5 \land y.f = 4\} \lor$

$\{t = 0 \Rightarrow x \neq y \land x.f = 4 \land y.f = 5\}$
Using the rule CONEFF, we derive:

\[ \vdash \{ t \neq 0 \land x \neq y \land x.f = 4 \land y.f = 4 \} x.f := 5[P'] \]
\[ \text{[region}(x.f) \]  
\[ \text{(2)} \]

and

\[ \vdash \{ t = 0 \land x \neq y \land x.f = 4 \land y.f = 4 \} y.f := 5[P'] \]
\[ \text{[region}(y.f) \]  
\[ \text{(3)} \]

Consider the formula (2). Since

\[ \vdash \{ t = 0 \land x \neq y \land x.f = 4 \land y.f = 4 \} y.f := 5[P'] \]
\[ \text{[region}(y.f) \]  
\[ \text{(4)} \]

is vacuously true, we can use rule IF and derive to

\[ \vdash \{ t \neq 0 \land x \neq y \land x.f = 4 \land y.f = 4 \} S[P'] \]
\[ \text{[region}(x.f) \]  
\[ \text{(5)} \]

Similarly, we can derive (3) to

\[ \vdash \{ t = 0 \land x \neq y \land x.f = 4 \land y.f = 4 \} S[P'] \]
\[ \text{[region}(y.f) \]  
\[ \text{(6)} \]

Using the rule CONEFF, we can prove \{P\} S[P'] \[x\].

We do backward reasoning:

Approach 1 with the rule IF:

Using the rule IF, we need to prove

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t \neq 0 \} x.f := 5[P'] \]
\[ \text{[region}(x.f) \]  
\[ \text{(7)} \]

and

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t = 0 \} y.f := 5[P'] \]
\[ \text{[region}(y.f) \]  
\[ \text{(8)} \]

Consider the formula (7), since \( x \neq y \land x.f = 4 \land y.f = 4 \land t \neq 0 \), using the rule CONMASK1, the proof obligation can be discharged to:

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t \neq 0 \} x.f := 5[P'] \]
\[ \text{[region}(x.f) \]  
\[ \text{(9)} \]

Let \( Q \) be \( x \neq y \land y.f = 4 \land t \neq 0 \) that is the frame. Let \( \delta \) be \textbf{reads} \( x,y,y.f,t \). Since

\[ x.f = 4 \not\vdash \delta \text{frm Q} \]
\[ \text{(10)} \]

and

\[ x \neq y \land x.f = 4 \land y.f = 4 \land t \neq 0 \Rightarrow \delta /: \text{modifies region}(x.f) \]
\[ \text{(11)} \]

Using the rule FRAME, the proof discharged to

\[ \vdash \{ x.f = 4 \} x.f := 5[x.f = 5] \text{[region}(x.f) \]
\[ \text{(12)} \]

Using the rule FIELDDUPD, one can prove (12). The formula (8) can be proved in a similar way.

Approach 2 with the rule CONEFF:

Usint the rule CONEFF, we need to prove

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t \neq 0 \} S[P'] \text{[region}(x.f) \]
\[ \text{(13)} \]

and

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t = 0 \} S[P'] \text{[region}(y.f) \]
\[ \text{(14)} \]

Consider the proof of the formula (13). Using the rule IF, one need to prove

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t \neq 0 \} x.f := 5[P'] \]
\[ \text{[region}(x.f) \]  
\[ \text{(15)} \]

and

\[ \vdash \{ x \neq y \land x.f = 4 \land y.f = 4 \land t = 0 \} y.f := 5[P'] \]
\[ \text{[region}(y.f) \]  
\[ \text{(16)} \]

The formula (16) is vacuously true. The other formula can be proved by the rules FRAME and FIELDDUPD. Consider the example in Fig. 1; the execution of \( S_1 \) causes the write effect, region\{this.fpt\}, and the execution of \( S_2 \) causes the write effect, region\{Find(key).val\}. So we can prove that the frame condition is \textbf{if} \text{Find(key)} = \textbf{null} then region\{this.fpt\} else region\{Find(key).val\}. Moreover, a more precise frame condition not only means fewer locations that may be modified in some states, but also more locations are not changed and the validity of more assertions can be preserved. Consider the FRAME rule in Fig. 18. Let \( Q \) be \( o.data = 5 \land o.valid = \text{false} \), and \( \epsilon \) be \textbf{modifies if} \text{o.valid then region}\{o.data\} \text{else region}\{\}, which is reduced to \textbf{modifies region} by the similar analysis in section 4.1. \( \delta = \text{reads o.o.data,o.valid} \), which frames \( Q \). So \( \delta /: \text{modifies region}\{\} \) by the definition of separator in Fig. 17. Therefore we can prove \( Q \) is the frame. If \( \epsilon \) approximates to just \textbf{region}\{o.data\} without conditions, we cannot prove \( Q \) is the frame.

We introduce two rules CONMASK1 and CONMASK2 that drop conditional frames. The rule CONMASK1 says if \textbf{if E then RE1 else RE2} is in the frame condition, and \( E \neq 0 \) is true in the pre-condition, then it is sound to simplify the conditional frames to \( RE_1 \). The rule CONMASK2 is similar. One can always drop conditional frames by applying the CONMASK1 and CONMASK2 rules before applying the FRAME rule. Therefore, we can keep the FRAME rule unchanged.

We also revised the rules POSTTOFR and FRTOPOST. They manipulate conditional freshness effects. Note that the un-conditional freshness effects, fresh\{RE\}, can be considered as \textbf{if true then fresh\{RE\} else region}\{\}. The special variable, alloc, has type region, and contains all allocated locations in the heap. The keyword \textbf{old} denotes values in the pre-state. If one can prove that the postcondition of a statement, \( S \), implies that all fresh objects may be allocated in region \( RE_1 \) or \( RE_2 \) according to a complementarity conditions, \( E \neq 0 \) and \( E = 0 \). Then it is sound to add the effect \textbf{if E then fresh\{RE1\} else fresh\{RE2\}} to \( S \)’s effect. The rule FRTOPOST is the reverse of the rule POSTTOFR. If \textbf{if E then fresh\{RE1\} else fresh\{RE2\}} is the fresh effect, and \textbf{reads old(alloc)} separates \( \epsilon \) in the post-condition \( P' \), then it is sound to conjoin old\{E\} \( \neq 0 \Rightarrow RE_1 \} \text{old(alloc)} and old\{E\} = 0 \Rightarrow RE_2 \} \text{old(alloc)} to the post-condition \( P' \). The rules VARMASK1, VARMASK2, FIELDMASK1 and FIELDMASK2 drop write effects. Consider the example of proving \{true\} if

\[ \text{[15]} \]

\[ \text{[16]} \]
true then $x := x\{true\}$. Using the rule ASSIGN [4], CONSEQ [4] and the rule IF, one can derive:

\[
\{true\} \text{if true then } x := x \{true\} \text{if true then } x.
\]

(17)

The variable $y$ is not written by the statement. And in the pre-state and post-state, $x$ is equal to the value of $y$ that is not changed. So, $P \lor P' \Rightarrow x = y$ is valid. And Therefore, using the rule VARMASK1, one can derive $\{true\} \text{if true then } x := x \{true\}$ from (17). Similarly, FIELDMASK1 and FIELDMASK2 are used to prove, e.g., $\{x.f = 0\} \text{if true then } x.f := 0\{true\}$. 

Definition 3 defines the validity of correctness judgment.

**Definition 3.** (Validity) The judgment $\Gamma \vdash \{P\} S \{Q\} [\epsilon]$ is valid, written $\sigma \models^\Gamma \{P\} S \{Q\} [\epsilon]$, if and only if: if $\sigma \models^\Gamma P, \sigma' = MS[\Gamma \vdash \{S\} : ok(\Gamma)](\sigma)$, and $\sigma' \neq \bot$, then $\sigma' \models^\Gamma Q$ and the effect from $\sigma$ to $\sigma'$ is covered by $\epsilon$.

**Theorem 1.** Every derivable correctness judgment is valid.

7. **EXAMPLE REVISITED**

Consider the client code in the introduction. Before $o.\text{sync()}$ is called, we have the state that satisfies $Q = \{o.data = 5 \land o.\text{valid} = false\}$. The postcondition of $o.\text{sync()}$, $P'$, is $o.\text{valid} = o.\text{data} = 5$, and the frame condition, $\epsilon$, is $o.\text{valid} = o.\text{data}$. Apply the rule CONMASK2, we obtain the new frame, $\epsilon'$, that is $\text{region}[\cdot]$. $Q$’s read effects, $\delta$, is $\{o.\text{data}, o.\text{data}\}$. So $\delta / \epsilon$. Therefore, we can apply the FRAME rule, and conclude that $Q$ is valid after $o.\text{sync()}$ is called. Therefore the assertion $\text{assert } o.\text{data} = 5$ is valid.
