Abstract—Application delays caused by abnormal tasks are common problems in big data computing frameworks. An abnormal task in Spark, which may run slowly without error or warning logs, not only reduces its resident node’s performance, but also affects other nodes’ efficiency.

Spark log files report neither root causes of abnormal tasks, nor where and when abnormal scenarios happen. Although Spark provides a “speculation” mechanism to detect straggler tasks, it can only detect tailed stragglers in each stage. Since the root causes of abnormal happening are complicated, there are no effective ways to detect root causes.

This paper proposes an approach to detect abnormality and analyzes root causes using Spark log files. Unlike common online monitoring or analysis tools, our approach is a pure off-line method that can analyze abnormality accurately. Our approach consists of four steps. First, a parser preprocesses raw log files to generate structured log data. Second, in each stage of Spark application, we choose features related to execution time and data locality of each task, as well as memory usage and garbage collection of each node. Third, based on the selected features, we detect where and when abnormalities happen. Finally, we analyze the problems using weighted factors to decide the probability of root causes. In this paper, we consider four potential root causes of abnormalities, which include CPU, memory, network, and disk. The proposed method has been tested on real-world Spark benchmarks. To simulate various scenario of root causes, we conducted interference injections related to CPU, memory, network, and disk. Our experimental results show that the proposed approach is accurate on detecting abnormal tasks as well as finding the root causes.

I. INTRODUCTION

With rapid growth of data size and diversification of workload types, big data computing platforms increasingly play more important role for solving real-world problems [6] [10] [11] [15]. Several outstanding frameworks are in active use today including Hadoop [1], Spark [2], Storm and Flink. Among them, the Apache Spark has arguably seen the widest adoption. It supports a fast and general programming model for large-scale data processing, in which Resilient Distributed Dataset (RDD) [14] are used to describe the input and intermediate data generated during the computation stages. RDDs are divided into different blocks, called partitions, with almost equal size among different compute nodes. Apache Spark uses pipeline to distribute various operations that work on a single partition of RDD. In order to serialize the execution of tasks, Spark introduces stage. All tasks in the same stage execute the same operation in parallel.

Compute nodes may suffer from a huge of interferences from software (such as operating systems or other processes) or hardware, which leads to abnormal problems. For instance, we name a task an abnormal task or straggler when it encounters significant delay in comparison with other tasks in the same stage. In Spark, there is a mechanism named speculation to detect this scenario, in which such slow tasks will be re-submitted to another worker. Spark performs speculative execution of tasks till a specified fraction (defined by spark.speculation.quantile, which is 75% by default) of tasks must be complete, then it checks whether or not the running tasks run slower than the median of all successfully completed tasks in a stage. A task is a straggler if its current execution time is slower than the median by a given ratio (which is defined by speculation.multiplier, 1.5x by default). In this paper, we propose a different approach compared with Spark Speculation. In our method, we consider whole Spark stages and abnormal tasks happening in any life span could be detected. In addition, Spark’s report could be inaccurate because Spark uses only fixed amount of finished task durations to speculate the unfinished tasks.

When abnormal tasks (including stragglers) happen, the performance of Spark applications could be degraded. However, it is very difficult for users to detect and analyze the root causes. First, Spark log files are tedious and difficult to read, and there is no straight-forward way to tell whether abnormal tasks happen or not, even through stragglers can be reported when speculation is enabled. Second, when an abnormal scenario happen, there is few information about the error in log files so that it is difficult for users to see the concreted reasons that lead to the straggler problem. Third, even online tools can monitor the usage and status of system resource such as CPU, memory, disk, and network, these tools do not directly cooperate with Spark, and users still need many efforts to scrutinize root causes based on their reporting. In addition, these monitoring tools usually carry overhead and may slow down Spark’s performance. Abnormal tasks could be caused by many reasons, where most of them are resource contentions [4] by CPU, memory, disk, and network. Our motivation is to help users find root causes of abnormal tasks by analyzing only Spark logs.

In this paper, we propose an off-line approach to detect abnormal tasks and analyze the root causes. Our method is
based on a statistical spatial-temporal analysis for Spark logs, which consists of Spark execution logs and Spark garbage collection logs. There are four steps to detect the root causes. (1) We parse Spark log files according to key words, such as task duration, data location, time stamp, task finish time, and generate a structured log data file. This step will eliminate all irrelevant messages and values. (2) We extract the related feature set directly from structured log file based on our experimental study. (3) We detect abnormal tasks from the log data by analyzing all relevant features. Specifically, we calculate the mean and standard deviation of all tasks in each stage, then determine abnormal tasks for each stage. (4) We generate factor combination criteria for each potential root cause based on analyzing their weighted factor in training datasets. Thus, our approach can effectively determine the proper root causes for given abnormal tasks.

The major contributions of this paper are as follows:

- The approach can accurately locate where and when abnormal tasks happen based on analyzing only Spark logs.
- Our offline approach can detect root causes of abnormal tasks according to Spark logs without any monitoring data, thus it does not have any monitoring overhead.
- It provides an easy way for users to deeply understand Spark logs and tune Spark performance.
- It gives an reasonable probability result for root cause analysis.

II. SPARK ARCHITECTURE

A. Background

Apache Spark is a fast and general engine for large-scale data processing. In order to achieve scalability and fault tolerance, Spark introduces an abstraction called resilient distributed dataset (RDD), which represents a read-only collection of objects partitioned across a set of machines that can be rebuilt if a partition is lost. When an application is submitted to Spark, the cluster manager will allocate compute resource according to the requirement of the application, then Spark scheduler distributes tasks to executors, and tasks will be executed in parallel. During this process, Spark driver node will monitor the status of executors and collect the tasks results from the worker nodes. In order to parallelize a job, Spark scheduler divides an application into a series of stages based on data dependence. In each stage, all tasks do not have data dependence and execute the same function.

B. The Framework of Spark Logging

Spark driver and executors record the status of executor and collection of execution information about tasks, stages, and job, which are the source of Spark logs.

Each Spark executor contains two log files, Spark execution log which record by log4j [5] and Spark garbage collection (GC) log, which are the outputs by stderr and stdout, respectively. Each of worker nodes and master nodes has its own log files. When an application is finished, we collect all Spark log files and aggregate them into an execution log and a GC log.

III. ABNORMAL TASK DETECTION AND ROOT CAUSE ANALYSIS

Spark log does not show abnormal tasks directly, thus users cannot locate abnormal tasks by simply searching keywords. This motivates us to design an automatic approach to help users detect the abnormalities and analyze the root causes.

A. Approach Overview

The workflow of our approach for abnormal detection and root cause analysis is shown in Figure 2.

1) Log preprocessing: We collect all Spark logs, including execution logs and Spark GC logs, from the driver node and all worker nodes. Then, we eliminate noisy data and reformat logs into more structured data.

2) Feature extraction: Based on Spark scheduling and potential abnormal task happening conditions, we screen execution-related, memory-related, CPU-related data to generate two matrices: execution log matrix and GC matrix. The details are illustrated in Section III-B.

3) Abnormal detection: We implement a statistical analysis approach based on the analysis of four kinds of features, including task duration, timestamps, GC time, and other task-related features, to determine the degree of abnormal tasks and locate their happening. The details are discussed in Section III-C.
4) **Root cause detection**: Instead of qualitatively deciding the exact root causes that lead to the abnormals, we quantitatively measure the degree of abnormals by a weighted combination of certain specific cause-related factors. The details are shown in Section III-E.

**B. Feature Execution**

According to Spark scheduling strategy, we define and classify all features into three categories, namely, execution-related, memory-related, and CPU-related, which are shown in Table I. For example, the execution-related features can be extracted from Spark execution logs, including task ID, task duration, task finished time, task started time, stage ID, and job’s duration. Spark GC log records all JVM memory usage, from which we can extract memory-related features such as heap usage, young space usage, as well as features related to system CPU usage such as system time and user time. These feature sets extracted from Spark execution log and GC log are shown in Table I.

**C. Abnormal Detection**

Adopting Spark speculation may bring false negatives in the process of abnormal detection. Hence, we provide a more robust approach to locate where stragglers happen and how long they take. We will also consider about special scenarios, for example, different stages are executed in sequence or in parallel.

One basic justification of abnormal tasks is that the running time of abnormal tasks is relatively longer than the normal ones. [4] uses “mean” and “median” to decide the threshold. However, in order to seek a more reasonable abnormal detection strategy, we consider not only the mean or median task running time, but also the distribution of the whole data, namely the standard deviation. In this way, we can get a macro-awareness on the task’s execution time, and then based on the distribution of data, a more reasonable threshold can be set to differentiate abnormals from the normal ones. The abnormal detection mainly includes the following two issues.

1. **Comparing task running time on different nodes**

We compare task execution time on different nodes in the same stage. Let $T_{task_{i,j,k}}$ denote the execution time of task $k$ in stage $i$ on node $j$. Let $avg_{stage_{i}}$ denote the average execution time of all tasks, which belong to different nodes but in the same stage $i$.

$$avg_{stage_{i}} = \frac{1}{J} \sum_{j=1}^{J} K_j \sum_{k=1}^{K_j} T_{task_{i,j,k}}$$

(1)

Work flow where $J$ and $K_j$ are the total number of nodes and the number of tasks in node $j$, respectively.

Similarly, the standard deviation of task execution in stage $j$ of all nodes is denoted as $std_{stage_{j}}$. Abnormal tasks are determined by the following conditions:

$$task_k \begin{cases} 
\text{abnormal} & T_{task_k} > avg_{stage_{i}} + k*std_{stage_{i}} \\
\text{normal} & \text{otherwise}
\end{cases}$$

(2)

where $k$ is a factor that controls the threshold for abnormal detection. In this paper, we set it to 1.5 by default for fair compare with Spark provided speculator.

Figure 3 (c) shows abnormal detection process in Wordcount under CPU interference. Figure 3 (a) and (b) are two stages inside the whole application. Moreover, inside each of the stage, purple-dot line is the abnormal threshold determined by Eq. (1), and the black dot-line indicates the threshold calculated by Spark speculation. For all tasks within a certain stage, the execution time above that threshold are detected as abnormals; otherwise, they are normals. Figure 3 (d) displays memory occupation along the execution of its corresponding working stages.

2. **Locating abnormal happening**

After all tasks are properly classified into “normal” and “abnormal”, the whole time line are labeled as a vector with binary number (i.e., 0 or 1, which denote normal and abnormal, respectively). To smooth the outliers (for example, 1 appears in many continuous 0) inside each vector, which could be an abrupt change but not consistent abnormal base, we then empirically set a sliding window with size of 5 to filter this vector. If the sum of numbers inside the window is larger than 2, the number in the center of the window will be set to 1, otherwise 0.

The next step is to locate the start and end time of this abnormal task. Note that, as Spark logs record the task finishing time but not the start time, so we locate the abnormal task’s start time as the recorded task finishing time minus its execution time. Moreover, for abnormal detection in each stage, the tasks are classified into two sets. One is for the initial tasks whose start time stamps are the begin of each stage, as these tasks often have more overhead (such as loading code and Java jar packets), and the execution time usually operates much longer than its followings. Another set consists of the rest tasks. Our experiments show that this classification inside each stage can lead to a much accurate abnormal threshold. In this way, our abnormal detection method can not only detect whether abnormals happen, but also locate where and when they happen.

**D. Factors Used for Root Causes Analysis**

After abnormals are located, we analyze their root causes inside that certain area. For different root causes, we use different features in Spark log matrix and GC matrix to determine criteria to decide the root causes. Specifically, for each root cause analysis, we use the combination of weighted factors to define the degree of probability of each root cause. In all normal cases the factor should equal to 1, and if an abnormal tends to any root cause, the factor will become much bigger than 1. The factors are denoted as $a,b,c,d,e,f,g$ for weight calculating. All of the indexes which are used in our factors’ definition are listed here:

Figure 3. Abnormal detection under CPU interference in the experiment of WordCount: (a) Abnormal detection result in Stage-1. (b) Abnormal detection result in Stage-2. (c) Spark execution log features for abnormal detection in the whole execution. (d) Spark GC log features for abnormal detection in the whole execution.

\[ a = \frac{k_j}{J-1 \left( \sum_{j=1}^{J} k_j \right) - k_j} \]  \hspace{1cm} (3)

where \( k_j \) indicates the number of tasks in node \( j \), and \( J \) is the total number of nodes in the cluster. Here, we assume that node \( j' \) is abnormal.

1. **Degree of Abnormal Ratio (DAR)**

Eq. (3) indicates the degree of abnormal ratio in a certain stage, as defined in Eq. (3).

2. **Degree of Abnormal Duration (DAD)**

The average task running time should also be considered, as the abnormal nodes often record longer task running time.
3. Degree of CPU Occupation (DCO)

This factor $c$ shown in Eq. (6) is used for expressing the ratio between the wall-clock time and the real CPU time. In the normal multiple-core environment, “realTime” is often less than “sysTime+UserTime”, because GC is usually invoked in multi-threading way. However, if the “realTime” is bigger than “sysTime+UserTime”, it may indicate that the system is very busy. We choose a Max value across nodes as the final factor.

$$c = \max_{j \in J}(\text{avg}(\frac{\text{realTime}_{i,j}}{\text{sysTime}_{i,j} + \text{userTime}_{i,j}}))$$  \hspace{1cm} (6)

4. Memory Changing Rate (MCR)

Eq. (7) indicates the gradient of GC curve. Under CPU, memory, and Disk interference, the interfered node’s GC curve will change slower than the normal nodes’ GC curve, as shown in Figure 5. $k_{\text{stable}}$ and $k_{\text{end}}$ are the gradients of the connected lines between start position (the corresponding memory usage at abnormal starting time) to the stable memory usage position and the start position to the abnormal memory end position (both the abnormal start and end time are obtained in the previous section) respectively. The reason we conduct this equation is that the interfered node uses less memory than normal nodes under interference. In this way, we use the maximum value of $k_{\text{stable}}$ in the whole cluster ($k_{\text{stable}}$ of normal node) to divide the minimums $k_{\text{end}}$ in the whole cluster (interfered node) to get the value of this factor.

$$d = \frac{\max_{j \in J}(k_{\text{stable}})}{\min_{j' \in J}(k_{\text{end}})}$$  \hspace{1cm} (7)

5. Degree of Task Delay (DTD)

For network interference, the task execution time will be affected when data transmission is delayed. Moreover, a Spark node often accesses data from other nodes, which leads to network interference propagation. Based on these facts, if network interference happens inside the cluster, the whole nodes will be affected, as shown in Figure 6, which is the location of our detected interference. Let $a$ be a factor that describes the degree of interference.

$$e = \exp(J \times \prod_{j=1}^{J} \text{abn}_{\text{prob}_{j}})$$  \hspace{1cm} (8)

Where $\text{abn}_{\text{prob}_{j}}$ indicates the ratio of abnormal that we detect for each node $j$ inside that area. The reason that we use the product of abnormal ratio other than the sum of them is that only when all nodes are with a portion of abnormal should we identify them with a potential of network interference, or if sum is used, we cannot detect this joint probability. Meanwhile, the exponential is to make sure that the final factor $e$ is no less than 1. In this way, the phenomenon of error propagation will be detected and quantified, which can only be shown in the cluster with network interference injection.

6. Degree of Memory Changing (DMC)
As network bandwidth is limited or the network speed slows down, when one node get affected by that interference, the task will wait for their data transformation from other nodes. Hence, CPU will wait, and data transfer rate becomes low. As shown in Figure 7.

![Figure 7](image)

**Figure 7.** Network interference is injected after WordCount has been executed for 30s, and continuously impacts for 120s.

The nodes with CPU interference often have a relatively lower computation capacity, which leads to less tasks allocated and longer execution time for tasks on it. Factors $a$ and $b$ are used to test if the interference is CPU or not, because CPU interference can reduce the number of scheduled tasks and increase the abnormal tasks’ execution time. Factor $c$ indicates the degree of CPU occupation, and CPU interference will slow down the performance compared to normal cases. Factor $d$ is used to measure memory changing rate, because CPU interference may lead memory change to become slowly than other regular nodes.

For the network-related interferences, because of its propagation, the original interfered node will often recover earlier. So our approach is to detect the first recovered node as the initial network-interfered node, and the degree $b$ quantitatively describes the interference. When network interference occurs, tasks are usually waiting for data delivery (factor $e$), the memory monitored by GC log $f$ is usually unchanged.

For the memory-related interferences, when memory interference is injected into the cluster, we can even detect a relatively lower CPU usage than other normal nodes. Considering this, the task numbers (factor $a$) and task duration (factor $b$) are also added to determine such root causes with certain weights. Moreover, the memory interference will impact memory usage, and the factor $d$ should be considered for this root cause detection.

To determine disk interferences, we introduce the factor $g$ to measure the degree of disk interference. The task set scheduled at the beginning of each stage could be affected by disk I/O. Therefore, these initial tasks on disk I/O interfered nodes behave differently from other nodes’ initial tasks beginning tasks (factor $g$). CPU will become busy, and memory usage is different with other nodes’. Therefore, the memory changing rate (factor $c$) and CPU Occupation (factor $d$) are also used to determine such root causes.

After deciding the combination of factors for each root cause, we give them weights to determine root causes.
accurately. Here, all weights are between 0 and 1, and the sum of them for each root cause is 1. To decide the values of weights, we use classical liner regression on training sets that we obtained from experiments on WordCount, Kmeans, and PageRank, which are discussed in more details in Section IV.

\[
\begin{align*}
CPU &= 0.3 \times a + 0.3 \times b + 0.2 \times c + 0.2 \times d \\
Memory &= 0.25 \times a + 0.25 \times b + 0.5 \times d \\
Network &= 0.1 \times b + 0.4 \times e + 0.5 \times f \\
Disk &= 0.2 \times c + 0.2 \times d + 0.6 \times g
\end{align*}
\]

Then, Eq. (12) is proposed to calculate the final probability that the abnormal belongs to each of the root causes.

\[
probability = 1 - \frac{1}{\text{factor}}
\]

IV. EXPERIMENTS

In this section, we present the experimental results on our abnormal detection and the root cause analysis in three Spark applications, i.e., WordCount, Kmeans, and PageRank which are provided by sparkbench [7].

A. Experimental Setup

To evaluate the performance of our proposed approach, we build an Apache Spark Standalone Cluster with four compute nodes, in which each compute node has a hardware configuration with Intel Xeon CPU E5-2620 v3 @ 2.40GHz, 16GB main memory, 1 Gbps Ethernet, and CentOS 6.6 with kernel 2.6. Apache Spark is v2.0.2.

B. Interference Injection

1) CPU: We spawn a bunch of processes to compete with Apache Spark jobs for computing resources, which triggers straggler problems in consequence of limited CPU resource.

2) Memory: We run a program that requests a significant amount of memory to compete with Apache Spark jobs. Thus, Garbage Collection will be frequently invoked to reclaim free space.

3) Disk: We simulate disk I/O contention using “dd” command to conduct massive disk I/O operations to compete with Apache Spark jobs.

4) Network: We simulate a scenario where network latency has a great impact on Spark. Specifically, we use “tc” command to limit bandwidth between two computing nodes.

C. Experimental Result Analysis & Evaluation

We conduct experiments on three benchmarks, WordCount in Spark package, Kmeans and PageRank in SparkBench [7]. We run each of the benchmarks 20 times with simulated interference injection.

Table III summarizes the probability results of our root cause detection approach. For the first step, totally 320 abnormal cases are created, out of which 38 are detected as normal (accuracy: 88.125%). Among these mis-classified cases, 29 are from memory fault injection and the rest 9 are from disk IO. Meanwhile, additional 60 normal cases are also put into our approach for root cause detection, and no one is reported as abnormal. We also check the normal cases’ abnormal factors to demonstrate the effectiveness of our approach. In all three benchmarks, the impact of CPU interference is significant, and tasks under CPU interference can be detected as abnormal with high probability. For memory interference, its probability is not significant because memory interference has less direct effect on Spark tasks, not like root causes. Injecting significant memory interference into one node will cause the whole application crash because the executers of Spark will fail if without enough memory. For network interference, the results show that the proposed approach gives a high probability. Lastly, disk interference shows a high probability in disk root causes. Worth mentioning here, for all different root causes, the detected probability of CPU are always high, because all root causes will eventually affect the efficiency of CPU.

D. Discussion

Our approach is only tested on clusters with injecting interference on a single node. In order to show considerable effect, the interference will last a while. Additionally, as our approach is based on the task analysis inside each stage, it requires the target application with a certain amount of task partitions for each stage. Furthermore, our approach would be less suitable for analyzing user’s log with different Garbage Collectors such as G1, CMS, and the new version of Spark log with different Spark schedulers.
V. RELATED WORK

Abnormal tasks could lead to performance degradation in the big data computing frameworks and their root causes are complicated. Ananthanarayanan et al. [3] classified root causes into three categories: machine characteristics, which are the main reason, such as CPU usage, memory availability, and disk failure; network characteristics faults like the network bandwidth limitation and package drop; the internals of the execution environment such as data-work partitioning. Garbagan man et al. [4] proposed that most common cause for abnormal occurrence is server resource utilization and data skew problem only takes 3% of total root causes. Therefore, we consider machine resources include CPU, memory, network, and disk as main root causes to analyze, and ignore data skew.

There are two kinds of approaches in abnormal detection, online and off-line. Some monitoring-related online approaches have been investigated. For example, Ananthanarayanan et al. [3] provide a tool called MANTRI that monitors tasks and outliers using cause- and resource-aware techniques. MANTRI uses real-time progress to detect outliers in their lifetime. Spark and Hadoop themselves provide an on-line “speculation”, which is a built-in component to detect stragglers. There are many off-line approaches analyze log to locate the error event positions [8] [9] [14]. Moreover, Xu et al. [13] use an automatic log parser to parse source code and combine PCA to detect anomaly, it is based on abstract syntax tree (AST) to analyze source code and uses machine learning to train data. Tan et al. [12] provides an approach to analyze Hadoop log by extracting state-machine views of a distributed system’s execution. Moreover, it combines control-flow and data-flow generated from debug log to catch normal system events and errors. In our approach, we extract features directly from log, but do not change any level of logging. And Xu et al. [4] provide an experiment-based approach to determine root causes of stragglers using an integrated off-line and online model.

VI. CONCLUSIONS AND FUTURE WORK

In this paper, we propose a novel approach for Spark log analysis, and it identifies abnormalities by combining both Spark log and GC log, and then analyze the root causes by weighted factors without using additional system monitoring information. Moreover, our approach can also identify the root causes of abnormalities with probability.

In the future work, we will consider more complex scenarios, such as multiple interferences happened in parallel, so as to make our framework more robust to find root causes under more complicated scenarios.
