*Abstract*—We consider a multi-cluster, multi-hop packet radio network architecture for wireless systems which can dynamically adapt itself with the changing network configurations. Due to the dynamic nature of the mobile nodes, their association and dissociation to and from clusters perturb the stability of the system, and hence a reconfiguration of the system is unavoidable. At the same time it is vital to keep the topology stable as long as possible. The clusterheads, which form a *dominant set* in the network, decide the topology and are responsible for its stability. In this paper, we propose a *weighted clustering algorithm* (WCA) which takes into consideration the ideal degree, transmission power, mobility and battery power of a mobile node. We try to keep the number of nodes in a cluster around a pre-defined threshold to facilitate the optimal operation of the medium access control (MAC) protocol. Our clusterhead election procedure is not periodic as in earlier research, but adapts based on the dynamism of the nodes. This on-demand execution of WCA aims to maintain the stability of the network, thus lowering the computation and communication costs associated with it. Simulation experiments are conducted to evaluate the performance of WCA in terms of the number of clusterheads, *reaffiliation* frequency and dominant set updates. Results show that the WCA performs better than the existing algorithms and is also tunable to different types of ad hoc networks.

## I. INTRODUCTION

Current cellular wireless networks solely rely on the wired backbone by which all base stations are connected, implying that networks are fixed and constrained to a geographical area within a pre-defined boundary. Deployment of such a network takes time and cannot be set up in times of utmost emergency. Therefore, mobile multi-hop radio networks, also called *ad hoc* networks or *peer-to-peer* networks, play a critical role in places where a wired (central) backbone is neither available nor economical to build, such as law enforcement operations, battle field communications, disaster recovery situations, and so on. Such situations demand a network where all the nodes including the base stations are potentially mobile, and communication must be supported untethered between any two nodes.

A multi-cluster, multi-hop packet radio network architecture for wireless systems should be able to dynamically adapt itself with the changing network configurations. Certain nodes, known as *clusterheads*, are responsible for the formation of *clusters* (analogous to *cells* in a cellular network) and maintenance of the topology of the network. The set of clusterheads, is known as a *dominant set*. A clusterhead does the resource allocation to all the nodes belonging to its cluster. Due to the dynamic nature of the mobile nodes, their association and dissociation to

and from clusters perturb the stability of the network and thus reconfiguration of clusterheads is unavoidable. This is an important issue since frequent clusterhead changes adversely affect the performance of other protocols such as scheduling, routing and resource allocation that rely on it. Choosing clusterheads optimally is an NP-hard problem [2]. Thus existing solutions to this problem are based on heuristic (mostly greedy) approaches and none of them attempts to retain the topology of the network [2], [4]. We believe a good clustering scheme should preserve its structure as much as possible when nodes are moving and/or the topology is slowly changing. Otherwise, re-computation of clusterheads and frequent information exchange among the participating nodes will result in high computation cost overhead.

The concept of dividing the geographical region into small zones has been presented implicitly in the literature as clustering [9]. A natural way to map a “standard” cellular architecture into a multi-hop packet radio network is via the concept of a virtual cellular network (VCN) [4]. Any node can become a clusterhead if it has the necessary functionality, such as processing and transmission power. Nodes register with the nearest clusterhead and become member of that cluster. Clusters may change dynamically, reflecting the mobility of the underlying network. The focus of the existing literature in this area has been on just partitioning the network into clusters [2], [3], [6], [7], [8], without taking into consideration the efficient functioning of all the system components. The lack of rigorous methodologies applicable to the design and analysis of peer-to-peer mobile networks has motivated in-depth research in this area. There have been solutions for efficient ways of interconnecting the nodes in such a way that the latency of the system is minimized while throughput is maximized [6]. Most of the approaches [2], [4], [6] for finding the clusterheads do not produce an optimal solution with respect to battery usage, load balancing and MAC functionality.

In this paper, we propose a *weighted clustering algorithm* (WCA) which takes into consideration the number of nodes a clusterhead can handle ideally (without any severe degradation of the system performance), transmission power, mobility and battery power of the nodes. Most of the existing clustering algorithms are invoked periodically but our algorithm is not periodic. Its invocation is adaptive based on the mobility of the nodes. More precisely, the election procedure is delayed as long as possible to reduce the computation cost. Frequent updates result in high information exchange among the nodes resulting in high communication overhead. We show by simulation experi-

This work is partially supported by Texas Advanced Research Program grant TARP-003594-013, Texas Telecommunications Engineering Consortium (TxTEC) and Nortel Networks, Richardson, Texas.

ments that our method yields better results as compared to the existing heuristics in terms of the number of reaffiliations and dominant set updates.

The rest of the paper is organized as follows. In Section 2, we present the existing approaches and their limitations. Section 3 proposes our new algorithm. Simulation results are presented in Section 4 while conclusions are offered in Section 5.

## II. PREVIOUS WORK

Several heuristics have been proposed to choose clusterheads in an ad hoc network. These include (i) Highest-Degree heuristic (ii) Lowest-ID heuristic and (iii) Node-Weight heuristic. In the assumed graph model of the network, the mobile terminals are represented as nodes and there exists an edge between two nodes if they can communicate with each other directly (i.e., one node lies within the transmission range of another). The performance of these heuristics were shown in [3], [6] by simulation experiments where mobile nodes were randomly placed in a square grid and moved with different speeds in different directions. Let us summarize below these heuristics.

### A. Highest-Degree Heuristic

This approach is a modified version of [10] which computes the degree of a node based on the distance between that node from others. A node  $x$  is considered to be a neighbor of another node  $y$  if  $x$  lies within the transmission range of  $y$ . The node with the maximum degree is chosen to be a clusterhead and any tie is broken by the node ids which are unique. The neighbors of a clusterhead become members of that cluster and can no longer participate in the election process. This heuristic is also known as the highest-connectivity algorithm.

Experiments demonstrate that the system has a low rate of clusterhead changes but the throughput of the system is low. Typically, each cluster was assigned some resources which was shared among the members of that cluster on a round-robin basis [6], [7], [8]. As the number of nodes in a cluster is increased, the throughput of each user drops and hence, a gradual degradation in the system performance is observed. This is the inherent drawback of the Highest-Degree heuristic since the number of nodes in a cluster is not bounded.

### B. Lowest-ID Heuristic

Gerla and Tsai [6] proposed a simple heuristic by assigning a unique id to each node and choosing the node with the minimum id as a clusterhead. However, the clusterhead can delegate its duties to the next node with the minimum id in its cluster. A node is called *gateway* if it lies within the transmission range of two or more clusters.

For this heuristic, the system performance is better compared to the Highest-Degree heuristic in terms of the throughput. Since the environment under consideration is mobile, it is unlikely that node degrees remain stable resulting in frequent clusterhead updates. The drawback of this heuristic is its bias towards nodes with smaller id which leads to the battery drainage

of certain nodes. Moreover, it does not attempt to balance the load uniformly across all the nodes.

### C. Node-Weight Heuristic

Basagni et al. [2], [3] assigned *node-weights* based on the suitability of a node being a clusterhead. A node is chosen to be a clusterhead if its node-weight is higher than any of its neighbor's node-weights. The smaller node id is chosen to break a tie.

To verify the performance of the system [2], the nodes were assigned weights which varied linearly with their speeds but with negative slope. Results proved that the number of updates required is smaller than the Highest-Degree and Lowest-ID heuristics. Since node weights were varied in each simulation cycle, computing the clusterheads becomes very expensive and there are no optimizations on the system parameters such as throughput and power control.

## III. OUR APPROACH

None of the above three heuristics leads to an optimal selection of clusterheads since each deals with only a subset of parameters which impose constraints on the system. For example, a clusterhead may not be able handle a large number of nodes due to resource limitations even if these nodes are its neighbors and lie well within its transmission range. Thus, the load handling capacity of the clusterhead puts an upper bound on the node-degree. In other words, simply covering the area with the minimum number of clusterheads will put more burden on the clusterheads. At the same time, more clusterheads will lead to a computationally expensive system. This may result in good throughput, but the data packets have to go through multiple hops resulting in high latency. In summary, choosing an optimal number of clusterheads which will yield high throughput but incur as low latency as possible, is still an important problem. As the search for better heuristics for this problem continues, we propose the use of a *combined weight* metric, that takes into account several system parameters like the ideal node-degree, transmission power, mobility and the battery power of the nodes.

We could have a fully distributed system where all the nodes share the same responsibility and act as clusterheads. However, more clusterheads result in extra number of hops for a packet when it gets routed from the source to the destination, since the packet has to go via larger number of clusterheads. Thus this solution leads to higher latency, more power consumption and more information processing per node. On the other hand, to maximize the resource utilization, we can choose to have the minimum number of clusterheads to cover the whole geographical area over which the nodes are distributed. The whole area can be split up into zones, the size of which can be determined by the transmission range of the nodes. This can put a lower bound on the number of clusterheads required. Ideally, to reach this lower bound, a uniform distribution of the nodes is necessary over the entire area. Also, the total number of nodes per unit area should be restricted so that the clusterhead in a zone can handle all the nodes therein. However, the zone based clus-

tering is not a viable solution due to the following reasons.

The clusterheads would typically be centrally located in the zone, and if they move, new clusterheads have to be selected. It might so happen that none of the other nodes in that zone are centrally located. Therefore, to find a new node which can act as a clusterhead with the other nodes within its transmission range might be difficult. Another problem arises due to non-uniform distribution of the nodes over the whole area. If a certain zone becomes densely populated then the clusterhead might not be able to handle all the traffic generated by the nodes because there is an inherent limitation on the number of nodes a clusterhead can handle. We propose to select the minimum number of clusterheads which can support all the nodes in the system satisfying the above constraints.

#### A. Basis for Our Algorithm

To decide how well suited a node is to be a clusterhead, we take into account its degree, transmission power, mobility and battery power. The following features are considered in our weighted clustering algorithm (WCA).

- The clusterhead election procedure is not periodic and invoked as rarely as possible. This reduces system updates and hence computation and communication costs.
- Each clusterhead can ideally support  $M$  (a pre-defined system threshold) nodes to ensure efficient MAC functioning. A high throughput of the system can be achieved by limiting or optimizing the number of nodes in each cluster.
- The battery power can be efficiently used within certain transmission range. Consumption of the battery power is more if a node acts as a clusterhead rather than an ordinary node.
- Mobility is an important factor in deciding the clusterheads. *Reaffiliation* occurs when one of the ordinary nodes moves out of a cluster and joins another existing cluster. In this case, the amount of information exchange between the node and the corresponding clusterhead, is local and relatively small. The information update in the event of a change in the dominant set is much more than a reaffiliation.
- A clusterhead is able to communicate better to its neighbors if they are closer to the clusterhead within the transmission range. This is due to signal attenuation with increasing distance.

#### B. Proposed Algorithm (WCA)

Based on the preceding discussions, we propose an algorithm which effectively combines all the system parameters with certain weighing factors, the values of which can be chosen according to the system needs. For example, power control is very important in CDMA networks, thus the weight of that factor can be made larger. The flexibility of changing the weight factors helps in applying our algorithm to various networks. The procedure for clusterhead selection is presented below. Its output is a set of nodes (dominant set) which forms the clusterheads for the network. According to our notation, the number of nodes that a clusterhead can handle ideally is  $M$ . The clusterhead election algorithm is invoked at the time of system activation and also when the current dominant set is unable to cover all the nodes.

#### Clusterhead Election Procedure

*Step 1:* Find the neighbors of each node  $v$  (i.e., nodes within its transmission range). This gives the *degree*,  $d_v$ , of this node.

*Step 2:* Compute the *degree-difference*,  $D_v = |d_v - M|$ , for every node  $v$ .

*Step 3:* For every node, compute the *sum of the distances*,  $P_v$ , with all its neighbors.

*Step 4:* Compute the running average of the speed for every node. This gives a measure of mobility and is denoted by  $M_v$ .

*Step 5:* Compute the time,  $T_v$ , of a node  $v$  during which it acts as a clusterhead.  $T_v$  indicates how much battery power has been consumed since we assumed that consumption of battery power is more for a clusterhead than for an ordinary node.

*Step 6:* Calculate a *combined weight*  $I_v = c_1 D_v + c_2 P_v + c_3 M_v + c_4 T_v$ , for each node  $v$ . The coefficients  $c_1, c_2, c_3$  and  $c_4$  are the weighing factors for the corresponding system parameters.

*Step 7:* Choose the node with a minimum  $I_v$  to be the clusterhead. All the neighbors of the chosen clusterhead can no longer participate in the election algorithm.

*Step 8:* Repeat Steps 2 to 7 for the remaining nodes not yet assigned to any cluster.

#### C. System Activation and Update Policy

When a system is brought up, every node  $v$  broadcasts its id which is registered by all other nodes lying within  $v$ 's transmission range, *tx.range*. It is assumed that a node receiving a broadcast from another node can estimate their mutual distance from the strength of the signal received. Thus, every node is made aware of its neighboring nodes and their corresponding distances. Note that these neighboring nodes are only the geographical neighbors and do not necessarily mean neighbors in the same cluster. Once the neighbors list is ready, our algorithm WCA chooses the clusterhead for the first time. Each node maintains a record of its status (i.e., whether or not it is a clusterhead). If it is a non-clusterhead node, then it should know the cluster it belongs to and the corresponding clusterhead.

Due to the dynamic nature of the system considered, the nodes as well as the clusterheads tend to move in different directions, thus disorganizing the stability of the configured system. So, the system has to be updated from time to time. The update may result in formation of new clusters. It may also result in nodes changing their point of attachment from one clusterhead to another within the existing dominant set, which is called *reaffiliation*. The frequency of update and hence reaffiliation is an important issue. If the system is updated periodically at a high frequency, then the *latest* topology of the system can be used to find the clusterheads which will yield a good dominant set. However, this will lead to high computational cost resulting in the loss of battery power or energy. If the frequency of update is low, there are chances that current topological information will be lost resulting in sessions terminated midway.

Every mobile node in any system (GSM or CDMA) periodically exchange control information with the base station. Similar idea is applied here, where all the nodes continuously monitor their signal strength as received from the clusterhead. When

the mutual separation between the node and its clusterhead increases, the signal strength decreases. In that case, the mobile has to notify its current clusterhead that it is no longer able to attach itself to that clusterhead. The clusterhead tries to hand-over the node to a neighboring cluster (existing clusterhead in the dominant set), this process being called a *reaffiliation*. The clusterhead of the reaffiliated node updates its member list. If the node goes into a region not covered by any clusterhead, then the clusterhead election algorithm is invoked and the new dominant set is obtained.

The objective of our clusterhead election algorithm is to minimize the number of changes in dominant set update. Once the neighbors list for all nodes are created, the degree-difference  $D_v$  is calculated for each node  $v$ . Also,  $P_v$  is computed for each node by summing up the distances of its neighbors. The mobility  $M_v$  is calculated by averaging the speed of the node. The total amount of time,  $T_v$ , it remained as a clusterhead is also calculated. All these parameters are normalized, which means that their values are made to lie in a pre-defined region. The corresponding weights  $c_1, c_2, c_3$  or  $c_4$  are kept fixed for a given system. The weighing factors also give the flexibility of adjusting the effective contribution of each of the parameters in calculating the *combined weight*  $I_v$ . For example, in a system where battery power is more important, the weight  $c_4$  associated with  $T_v$  can be made higher. It is to be noted that the sum of these weighing factors is 1. The node with the minimum total weight,  $I_v$ , is elected as a clusterhead. The elected clusterhead and its neighbors are no longer eligible to participate further in the remaining part of the election process. The election process is continued until every node is found to be either a clusterhead or a neighbor of some clusterhead.

#### IV. SIMULATION STUDY

We simulate a system with  $N$  nodes on a  $100 \times 100$  grid. The nodes could move in all possible directions with displacement varying uniformly between 0 to a maximum value ( $max\_disp$ ), per unit time. To measure the performance of our system, we identify three metrics: (i) the number of clusterheads, (ii) the number of reaffiliations, and (iii) the number of dominant set updates. Every time a dominant set is identified, its cardinality gives the number of clusterheads. The reaffiliation count is incremented when a node gets dissociated from its clusterhead and becomes a member of another cluster within the current dominant set. The dominant set update takes place when a node can no longer be a neighbor of any of the existing clusterheads. These three parameters are studied for varying number of nodes in the system, transmission range and maximum displacement.

##### A. Summary of Experimental Results

In our simulation,  $N$  was varied between 20 and 60, and the transmission range was varied between 0 and 70. The nodes moved randomly in all possible directions with a maximum displacement of 10 along each of the coordinates. Thus, the maximum Euclidean displacement possible is  $10\sqrt{2}$ . We assume that each clusterhead is ideally able to handle 10 nodes in its clus-

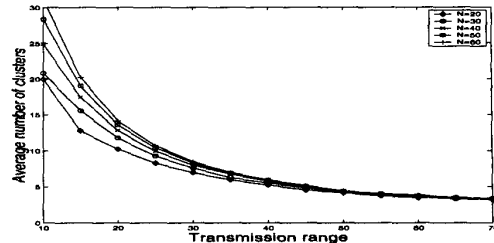

Fig. 1. Average number of clusters,  $max\_disp=5$

Fig. 2. Reaffiliations per unit time,  $max\_disp=5$

Fig. 3. Dominant set updates,  $max\_disp=5$

ter in terms of resource allocation. Therefore, the *ideal degree* was fixed at  $M = 10$  for the entire experiment. Due to this, the weight associated with  $D_v$  was rather high. The next higher weight was given to  $P_v$ , which is the sum of the distances. Mobility and battery power were given low weights. The values used for simulation were  $c_1 = 0.7, c_2 = 0.2, c_3 = 0.05$  and  $c_4 = 0.05$ . Note that these values are arbitrary at this time and should be adjusted according to the system requirements.

Figures 1-3 show the variation of three parameters, namely average number of clusterheads, reaffiliation per unit time and the number of dominant set update with varying transmission range and (constant)  $max\_disp$  of 5. Figure 1 shows the variation of the average number of clusterheads with respect to the transmission range. We observe that the average number of clusterheads decreases with the increase in the transmission range. This is due to the fact that, a clusterhead with a large transmission range will cover a larger area. Figure 2 shows the reaffiliations per unit time with respect to the transmission range. For low transmission range, the nodes in a cluster are relatively close to the clusterhead, and a detachment is unlikely. The number of reaffiliations increases as the transmission range increases, and reaches a peak when transmission range is between 20 and 30. Further increase in the transmission range results in a decrease in the reaffiliations since the nodes, in spite of their random motion, tend to stay inside the large area covered by the cluster-

Fig. 4. Average number of clusters,  $tx\_range=30$

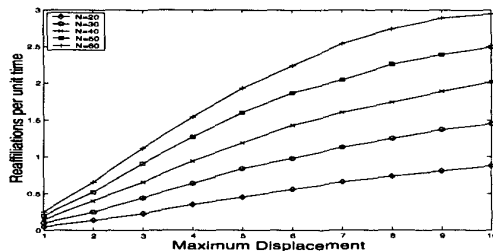

Fig. 5. Reaffiliations per unit time,  $tx\_range=30$

Fig. 6. Dominant set updates,  $tx\_range=30$

head. Figure 3 shows the number of dominant set updates with respect to the transmission range. For small transmission range, the cluster area is small and the probability of a node moving out of its cluster is high. As the transmission range increases, the number of dominant set updates decreases because the nodes stay within their cluster in spite of their movements.

Figures 4-6 show the variation of the same parameters but for varying  $max\_disp$  and constant transmission range of 30. Figure 4 shows that the average number of clusterheads is almost the same for different values of  $max\_disp$ , particularly for larger values of  $N$ . This is because, no matter what the mobility is, it simply results in a different configuration, but the cluster size remains the same. Figure 5 shows the reaffiliations per unit time with respect to the maximum displacement. As the displacement becomes larger, the nodes tend to move further from their clusterhead, detaching themselves from the clusterhead, causing more reaffiliation per unit time and more dominant set updates. This is shown in Figure 5 and Figure 6 respectively.

Figure 7 shows the relative performance of the Highest-Degree, Lowest-ID, Node-Weight heuristics and our algorithm (WCA) in terms of reaffiliations per unit time. The number of reaffiliations for our algorithm is at most half of the number obtained from the Lowest-ID. The main reason is that the frequency of invoking the clustering algorithm is lower in our case resulting in longer duration of stability of the network. Our algo-

rithm performs marginally better than the Node-Weight heuristics which, however, does not give the basis of assigning the weights to the nodes. Our algorithm describes a linear model which takes into consideration the four important system parameters in deciding the suitability of the nodes acting as clusterheads. It also provides the flexibility of adjusting the weighing factors according to the system needs.

Fig. 7. Comparison of reaffiliations,  $N=30$

## V. CONCLUSIONS

We propose an on-demand weighted clustering algorithm (WCA) which can dynamically adapt itself with the ever changing topology of ad hoc networks. The WCA has the flexibility of assigning different weights and takes into an account a combined effect of the ideal degree, transmission power, mobility and battery power of the nodes. The algorithm is executed only when there is a need, i.e., when a node is no longer able to attach itself to any of the existing clusterheads. Our algorithm performs significantly better than both of the Highest-Degree and the Lowest-ID heuristics. In particular, the number of reaffiliations for our algorithm is about 50% of the number obtained from Lowest-ID heuristic. Though our approach yields marginally better results than the Node-Weight heuristic, it considers more realistic system parameters and provides the flexibility of adjusting the weighing factors.
